Abstract

Since the last 20 years, modern heuristic algorithms and machine learning have been increasingly used for several purposes in accelerator technology and physics. Since computing power has become less and less of a limiting factor, these tools have become part of the physicist community's standard toolkit [1–5]. This paper describes the construction of an algorithm that can be used to generate an optimised lattice design for transfer lines under the consideration of restrictions that usually limit design options in reality. The developed algorithm has been applied to the existing SIS18 to HADES transfer line in GSI.

INTRODUCTION

Beside the necessary instrumentation, transfer lines usually consist of quadrupoles, dipoles, steerer magnets and buncher cavities. Sometimes the dipole positions are more or less fixed and therefore boundary conditions for the optimisation. For showing the idea, assumed that the geometry of the transfer line is given, which means that the number and position of the dipole magnets, as well as the start and end point. The goal is, to place 2 types of quadrupoles in between the dipoles such that a given particle distribution will be guided through the beam line with maximal transmission and focused on a target. The algorithm has been designed in such a way that minimizes both the power consumption and the required number of components.

GENOTYPE PARAMETERISATION

Without limiting the generality we assume to have in stock 2 standard quadrupoles Q_a and Q_b with associated lengths L_a and L_b , where $L_b > L_a$. Another assumption is, that each quadruple type is used for a different area of values for the normalized integrated field gradient $kl = B'l/(B\rho)$. These areas are distinct and do not overlap.

$$\begin{aligned} \text{area 1: } & (kl)_0 < |kl| \leq (kl)_a \\ \text{area 2: } & (kl)_a < |kl| \leq (kl)_b \end{aligned} \quad (1)$$

The simplest transfer line is a straight line and contains no further elements. Such a transfer line of a given length L can be divided in n sections of equal length. If we consider the solution with maximal number of the longest quadrupoles Q_b , in general the number n can not be bigger than L/L_b . In order to accommodate free space between the quadrupoles, one quadrupole is left out. Therefore the number of sections is

* s.reimann@gsi.de

$$n = \frac{L}{L_b} - 1 \quad (2)$$

In order to be able to use a metaheuristic optimization method such as a genetic algorithm [6], it is necessary to find a suitable parameterization for the corresponding problem. The parameters (an array of real numbers) are called the genes. For this work, the number of genes within a genome G is $2n$. Even genes ν_i represent the kl value of quadrupoles and odd genes μ_i represent the relative distance between the quadrupoles. All genes are real numbers.

$$G = \{\mu_1, \nu_1, \mu_2, \nu_2, \dots, \mu_n, \nu_n\} \quad (3)$$

PHENOTYPE CONSTRUCTION

The phenotype of the genome (3) is then constructed in the following way. For all ν_i , the constructed element E_i is either one of the standard quadrupoles or a drift line D , depending on the value of ν_i . For quadrupoles, ν_i is an expression of the kl value.

$$\begin{aligned} 0 < |\nu_i| \leq (kl)_0 & \implies E_i = D \\ (kl)_0 < |\nu_i| \leq (kl)_a & \implies E_i = Q_a \\ (kl)_a < |\nu_i| \leq (kl)_b & \implies E_i = Q_b \end{aligned} \quad (4)$$

In this manner it can be assured, that a quadrupole with more focusing power is used only, if more focusing power is really needed. The length of the constructed quadrupole (l_i) is defined by its type ($E_i = Q_a \implies l_i = L_a$, $E_i = Q_b \implies l_i = L_b$) and its strength can be calculated from

$$k_i = \frac{\nu_i}{l_i} \quad (5)$$

A discontinuity at the transition from Q_a to Q_b type quadrupoles can not be avoided, if both types have different lengths. The continuity can only be conserved for the kl value (Figs. 1, 2).

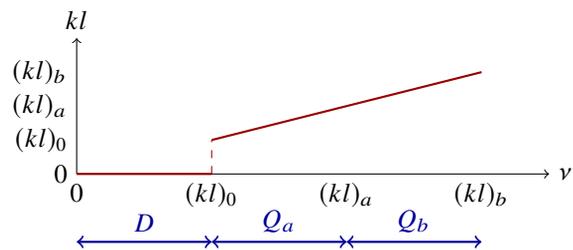

Figure 1: Dependence of kl on ν value.

Trivial Solution

In case of no additional aperture limitations besides the vacuum chamber, one can estimate the length of the transfer line where the beam (with the given particle distribution) goes through without losses.

$$y_{max} = 0.06 \text{ m} > 3\sigma_y + 3\sigma_{y'}L \implies 29.0 \text{ m} > L \quad (10)$$

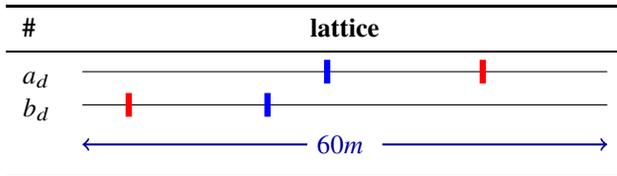

So, for a distance of $L = 25 \text{ m}$, the beam could be transported without additional focusing (assuming the σ_y and $\sigma_{y'}$ given in Table 2). The optimisation has been executed 20 times and in all cases, the algorithm found the optimal solution within less than 30 generations.

Doublet Solution

The next example is a 60 m transfer line, where a 100 % Transmission is not possible without additional focusing and hence there is no solution without quadrupoles.

Table 3 shows the 2 found solutions a_d and b_d . In any case the solution is a quadrupole doublet, in 70 % of the solutions the doublet starts using a vertical focusing (blue) and in 30 % with a horizontal focusing (red) quadrupole. The needed quadrupole strength for solution a_d is slightly lower than solution b_d .

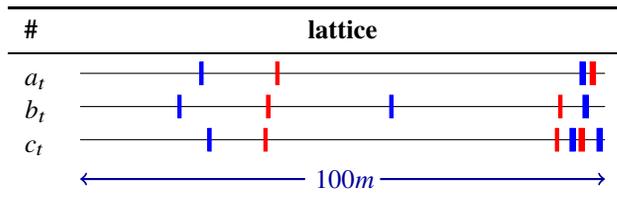

Table 3: Lattice Solutions for the 60 m Case

Target Focusing

Next considered case is a 100 m transfer line with a target circular aperture limitation of 5 mm (diameter) at the end of it. 3 solutions have been found (a_t , b_t and c_t) with 100 % transmission (see Table 4). The prevalence of solutions can be suppressed by varying the weights ω_i .

Table 4: Lattices for 100 m Transfer Line with Final Aperture Limitation

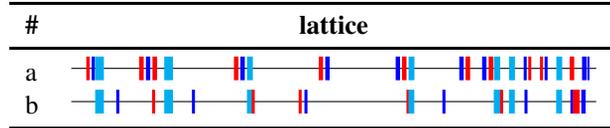

Transfer Line SIS18 to HADES Experiment

Our last case of study concerns the 160 m long transfer line that transports the beam from the SIS18 synchrotron to the HADES experiment. This transfer line is presently under review [9], as well as all the existing GSI transfer

lines [12], due to need for improving the transmission when running at high intensity [13]. The algorithm assumes a 5 cm long target with 2.2 mm diameter [14] at the end of the transfer line. The result obtained with 100 % transmission and smallest F is shown in Table 5 (b) against the present transfer line (a). The result looks quite different to the ex-

Table 5: Both HADES lattices (length ca. 160 m), the existing version (a) and the solution from the algorithm (b), cyan elements are bending dipoles.

isting version. The strength of element number (14 vs. 20) is much lower and the strong quadrupole (Q_b) is only used twice. Since intermediate foci are not excluded by the algorithm, they are part of the solution (Fig. 4). This beam line is also used for other purposes (the dipoles (cyan) distribute the beam also to other target stations) and for fast extraction, where the horizontal emittance is higher by a factor of 6, so some margin for deviations should be foreseen. This could easily be added to the algorithm by artificially limiting the aperture. At the moment the full aperture is used at some positions.

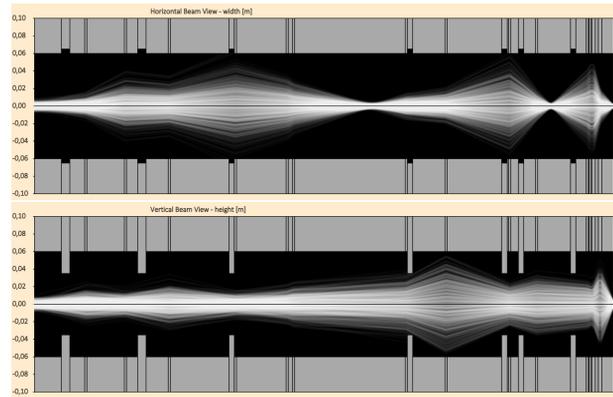

Figure 4: HADES lattice and optics, found by the algorithm, top = horizontal beam size, bottom = vertical beam size.

CONCLUSION

In all the considered transfer lines, the algorithm has found optimal solutions in terms of transmission while minimising energy consumption and number of elements. The algorithm will be further developed and investigated. Additional elements as buncher cavities are about to be included as well as high current effects. Next step is the comparison with experiments and existing solutions. All transfer lines of GSI/FAIR [15] will be reviewed and future lines could even be designed by the use of this algorithm.
